## Introduction

### 1.1 Acknowledgement

I would like to thank, Geir Hovland and Ilya Tyapin of The University of Agder, Norway for their contributions to this work. In addition, I want to acknowledge the support from The University of Agder for providing the resources needed to optimize the Gantry-Tau presented in this Thesis.

### 1.2 Abstract

This thesis presents the results of an investigation into modeling the kinematic errors of the Gantry-Tau Parallel Kinematic Manipulator. The calculations has been done onto the Gantry-Tau which has been designed in University Of Agder. Though, all the diminsions used in the simulation was tacken out from it. The Gantry-Tau consist of 3 parallel arms, 6 links, 12 joints, and 3 base linear actuators. Each arm contains one link that allows a translation movement. see Figure 1.1.

In this thesis, the 3-DOF Inverse kinematic model is applied to the Gantry-Tau. The links is considered to be the error parameters. 3 error parameters account for errors in the 3 arm lengths. Deeply, 6 error parameters account for error in 6 links. Functionalities from two different types of measurement equipment; laser interferometers and linear encoders have been utilised to create the error calibration systems. Simulation measurement is replaced with laser interferometeres.

The optimisation function for this implementation is built upon the basic geometric premises of the Gantry-Tau's structure. The Complex Research method was used to optimise the error calibration. This method will mirror the worst result arround the centroid and produce the best result for calibration. In other words, the method tries to make the RMSE value equal to zero. The result is given as a function of the generation against the RMSE value.

### 1.3 Scope of Study

This thesis looks at Error Kinematic Modeling and Calibration of the 3-DOF Gantry-Tau Parallel Kinematic Machine, which was first presented in Brogardh et al. (2005). Triangular mounted links give several advantages: they enable a reconfiguration of the robot and a larger reach is obtained in the extremes of the workspace. The researcher used computer based software like Matlab to provide a mathematical model as well as calibrations methods for the 3 DOF Gantry- Tau Parallel kinematic machines. This thesis report presents the development of tools for selection of measurements points according to the chosen measurement device.

The error on links length of the Gantry-Tau were the place of study. The links length were found by applying the IK modelling on the Gantry-Tau. The laser tracker experimentaly will read the position of the robot head. New measured link length will be calculated. The error between the link lengths and the measured link lengths will be calculated. A suitable optimization method will be applied to calibrate and minimize the error.

Figure 1.1: *Picture of the Gantry-Tau which used in this thesis.*

## 1.4 Motivation

The Error Kinematic Modeling and Calibration of The 3- DOF Gantry-Tau Parallel Kinematic Machine is a challenging area of study. Considering the area of optimization as well as calibration of the machine brings about the optimal performance. The modeling and calibration of the Gantry-Tau and other parallel manipulators is very important in application to its workspace.

The workspace of parallel manipulators with linear actuation beside the limits given by singularities and relative actuator placements is limited owing to three types of constraints: mechanical limit on the passive joints, interference between links and limited range in the length of linear actuators.

## 1.5 Organization of Thesis

The structure of this thesis is organized as follows:

- Chapter 1 contains acknowledgement, abstract, explain the scope of study, motivations and organisation of the thesis.
- Chapter 2 includes a brief literature about Gantry-Tau and PKM.
- Chapter 3 provides a mathematical model of the 3- DOF Inverse Kinematics of the Gantry- Tau.
- Chapter 4 looks the identification methods, where computer aided software were used in calibrations methods in this case Matlab was extensively used. This chapter will produce mainly the Complex Search Method.
- In Chapter 5, the Cartesian paths -Linear and Circle path- for identification have been optimised.
- Chapters 6 and 7 look at the simulations, results, conclusion of the thesis, and suggested farther work.

## Chapter 2

# Gantry-Tau PKM

The Parallel kinematic manipulator (PKM) is a closed-loop kinematic chain mechanism whereby the end-effector is connected in parallel [8]. The PKM consists of a more number of actuators than the number of controlled degrees of freedom of the end-effector. Closed-kinematic chains.

Motion platforms with six degrees of freedom, also known as hexapods, are possibly the most popular robotic manipulators used in simulation technology. This parallel mechanism was first described by V. E. Gough [7], who constructed an octahedral hexapod to test the behavior of tyres subjected to forces created during airplane landings. The first document providing a detailed description of this structure used as an airplane cockpit simulator was published in 1965 by D. Stewart [4] (hence the name of the structure). The Stewart platform is a closed kinematic system with six degrees of freedom and six adjustable length links. Figure 2.2 and Figure 2.1 are two examples of the Gantry-Tau PKM. Compared to other similar structures, its main advantage is high rigidity and a high input-power-to-device-weight ratio.

Figure 2.1: *Picture of the Gantry-Tau PKM.*

The traditional parallel kinematic manipulators (PKMs) have various applications in the industry due to its ability to occupy little space as compared to previous series kinematic manipulator.

The Tau family of PKMs was invented by ABB Robotics, [5]. The Gantry-Tau was designed to overcome the workspace limitations while retaining many advantages of PKMs such as low moving mass, high stiffness and no link twisting or bending moments. For a given Cartesian position of the robot each arm has two solutions for the inverse kinematics, referred to as the left- and right-handed configurations [3]. While operating the Gantry-Tau in both left- and right-handed configurations, the workspace will be significantly larger in comparison with both a serial Gantry-type robot and other PKMs with the same footprint and

Figure 2.2: *An example of the Gantry-Tau PKM.*

with only axial forces in the links of the arms.

The intended application of the robot is for machining operations requiring a workspace equal to or larger than of a typical serial type robot, but with higher stiffness. However, the robot can also be designed for very fast material handling and assembly or for high precision processes such as laser cutting, water jet cutting and measurement. Currently, there exist large gaps between the stiffness and dynamic properties of serial-type robots and many of the developed PKM prototypes. An industrial serial-type robot typically has a Cartesian stiffness in the range 1-2 Newton's per micron ( $N/\mu m$ ) and resonance frequencies below 10 Hz. A high-speed machining centre typically has stiffness larger than  $50N/\mu m$  and resonance frequencies larger than 50 Hz. Between these specifications there exists a large range of untapped application areas for PKMs. With higher stiffness and resonance frequencies compared to serial robots, PKMs can provide benefits such as reduced oscillations and overshoots which in turn can lead to economic benefits gained from reduced cycle-times

The Gantry-Tau PKM has the potential to meet the needs the small and medium size enterprises. Robots are used in large industry today to optimized work tasks that could have taken many years, and money to complete. Some of these examples are welding, fabrication in the automobile industry, the process and chemical industry, and more and more in the oil and gas industries.

For the small and medium enterprises (SMEs) produces a lot, a robot with more flexibility to fit constantly changing tasks is needed. There are very few industries today that have adjustable geometry. It is for that matter that a new robotic concept should be developed to meet the demands of the SMEs.[11]. This industry needs robots that can reconfigure according to the various tasks. The Gantry-Tau PKM will be ideal for the SMEs, it could be designed in a modular way so that the framework can be adjusted to specific tasks. [6].

There are however some short falls for the SMEs, that is every reconfiguration robots requires a new kinematic calibration. Recalibration could prove difficult for non or un trained personnel at the SMEs. It will therefore be prudent to provide the adequate tools for the personnel to easily deal with the multiple kinematic calibrations. Robots are normally delivered as an optimized entity either for commercial or research purposes. The geometry is not changed in both cases, the kinematic calibration, which is needed is performed only once by the trained personnel for this purpose or the research personnel.[9].

The kinematic calibration of Gantry-Tau robot includes several manually performance steps which need a well trained personnel who can re do the calibrations of changed geometry , such as the choice of measure-

ments poses or the analysis of measurements data. It cost SMEs some money to always bring in specialist to do these calibrations and recalibrations, so it will be prudent to give its own stuff a good understanding in dealing with these works.

Robot geometry: The Gantry-Tau PKM consists of three kinematic chains. Each chain includes a prismatic actuator, which is connected to the end-effector plate via a link cluster. The actuators are implemented as carts moving on tracks. The altogether six links are distributed to the link clusters in a 3-2-1 configuration and connected to carts and end-effector plate by spherical joints. The placement of the passive joints on plate and carts is such, that the links belonging to one cluster form parallelograms, which leads to a constant tool orientation. The robot has therefore three purely translational degrees of freedom (DOF).[2]

# Chapter 3

## 3-DOF Inverse Kinematics (IK)

### 3.1 Introduction

Both forward and inverse kinematics can give a solution to understand the geometry of motion of the Gantry-Tau. Forward kinematics is a mapping from joint space  $Q$  to Cartesian space  $W$ :

$$F(Q) = W \quad (3.1)$$

While inverse kinematics is a method to find the inverse mapping from Cartesian space  $W$  to joint space  $Q$ :

$$Q = F^{-1}(W) \quad (3.2)$$

It is important to identify the mobility of the Gantry Tau before starting the kinematic formulation. The Gantry-Tau is considered to be 5-DOF [13]. By the same concept let us consider that the telescopic links  $L_{2_2}$  and  $L_{3_3}$  shown in Figure 3.1 have a fixed length, the configuration will be 3-DOF in this case. In this section a 3-DOF IK will be discussed as it has been published in [10].

Figure 3.1: *The links and joints of the Gantry-Tau*

The 3-DOF Inverse Kinematics of the Gantry-Tau will be the best and simplest approach to use. It will not give any unknown variables and will be relatively easy to program. 3-DOF IK is a simplified model which reduces the geometric complexity of the structure. Assumption of fixed links  $L_{2_2}$  and  $L_{3_3}$  is taken in consideration, which can yield to assumption of reduces the links from 6 links to 3 links sharing the same

joint on the manipulated platform as shown in figure 3.2. The general case of 3-DOF configuration will be used on this work where 6 links is assumed which connect with specific offsets to the platform which shown in figure 3.3

Figure 3.2: *Simplified model of the Gantry-Tau*

### 3.2 Calculations of 3-DOF IK

To solve the IK for the Gantry-Tau, the calculations will be done from the Tool Centre Point (TCP) moving step by step toward the actuators.

Figure 3.3: *The Gantry Tau for 3-DOF*

By looking to Figure 3.3, The first step is to calculate the link lengths which are:

$$(L_1)^2 = (X_{Ap} - X_{Ab})^2 + (Y_{Ab} - Y_{Ap})^2 + (Z_{Ab} - Z_{Ap})^2 \quad (3.3)$$

$$(L_{2_1})^2 = (X_{Bp} - X_{Bb})^2 + (Y_{Bb} - Y_{Bp})^2 + (Z_{Bb} - Z_{Bp})^2 \quad (3.4)$$

$$(L_{3_1})^2 = (X_{Dp} - X_{Db})^2 + (Y_{Db} - Y_{Dp})^2 + (Z_{Db} - Z_{Dp})^2 \quad (3.5)$$

$X_{Ab}$ ,  $X_{Bb}$ ,  $X_{Db}$  are the actuators positions which are equal to  $q_1$ ,  $q_2$ ,  $q_3$  respectively. This leads to the following equation:

$$q_1 = \pm \sqrt{(L_1)^2 - (Y_{Ab} - Y_{Ap})^2 - (Z_{Ab} - Z_{Ap})^2} + X_{Ap} \quad (3.6)$$

$$q_2 = \pm \sqrt{(L_{2_1})^2 - (Y_{Bb} - Y_{Bp})^2 - (Z_{Bb} - Z_{Bp})^2} + X_{Bp} \quad (3.7)$$

$$q_3 = \pm \sqrt{(L_{3_1})^2 - (Y_{Db} - Y_{Dp})^2 - (Z_{Db} - Z_{Dp})^2} + X_{Dp} \quad (3.8)$$

Her it is noticed that for each actuator there are two possible solutions at a certine position of the TCP. In general we can say that every point can be reached by two positions of the actuator. To simplify this meaning it is called left-hand solution and right-hand solution. By practice this will give 8 possible solutions for every position of the TCP. This will be also a user input. The user should decide how can he reach a certine position. Figure 3.4 shows an example for the 8 possible solutions for a certine position.

Figure 3.4: The 8 possible configurations for the end-effector

The links lengths  $L$  and the distances between the actuators and the joint of base connections of the links  $b$  are fixed and known. To determine the actuators positions, the joint connections between links and platforms  $p$  must be found depending on  $TCP$  position. In general it can be defined that:

$$[ P ] = [ TCP ] + [ R_y ] [ OFFSET ] \quad (3.9)$$

This expression can be written in a clear way including the real variables:

$$\begin{bmatrix} X_{Ap} \\ Y_{Ap} \\ Z_{Ap} \end{bmatrix} = \begin{bmatrix} X_{TCP} \\ Y_{TCP} \\ Z_{TCP} \end{bmatrix} + [RotY] \begin{bmatrix} d_{AX} \\ d_{AY} \\ d_{AZ} \end{bmatrix} \quad (3.10)$$

$$\begin{bmatrix} X_{Bp} \\ Y_{Bp} \\ Z_{Bp} \end{bmatrix} = \begin{bmatrix} X_{TCP} \\ Y_{TCP} \\ Z_{TCP} \end{bmatrix} + [RotY] \begin{bmatrix} d_{BX} \\ d_{BY} \\ d_{BZ} \end{bmatrix} \quad (3.11)$$

$$\begin{bmatrix} X_{Dp} \\ Y_{Dp} \\ Z_{Dp} \end{bmatrix} = \begin{bmatrix} X_{TCP} \\ Y_{TCP} \\ Z_{TCP} \end{bmatrix} + [RotY] \begin{bmatrix} d_{DX} \\ d_{DY} \\ d_{DZ} \end{bmatrix} \quad (3.12)$$

Where  $TCP$  are the user input and  $OFFSETT$  is a known distances. Rotation around y-axis  $R_y$  must be found in order to know  $P$ . This guides us to the second step of IK which is foundation of the rotation around y-axis. Let us imagine a rotation of  $\beta$  angle around y-axis. which is shown in figure 3.5. An example is given to make it easier for understanding. The rotation is around y-axis so y coloumb will be fixed and equal to:

Figure 3.5: Rotaion of  $\beta$  around y-axis

$$\begin{bmatrix} \cdot & 0 & \cdot \\ \cdot & 1 & \cdot \\ \cdot & 0 & \cdot \end{bmatrix} \quad (3.13)$$

Let us consider a rotation of  $\beta= 90$  degree. Then X becomes -Z and Z becomes -X. This can easy replaces on the rotation array and it becomes:

$$\begin{bmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ -1 & 0 & 0 \end{bmatrix} \quad (3.14)$$

It is know that  $\sin 90 = 1$ ,  $\cos 90 = 0$ , and  $-\sin 90 = -1$ . The rotation array around y-axis will be :

$$RotY = \begin{bmatrix} \cos \beta & 0 & \sin \beta \\ 0 & 1 & 0 \\ -\sin \beta & 0 & \cos \beta \end{bmatrix} \quad (3.15)$$

Equation 3.15 shows that we still need to know  $\beta$ . Here, thinking of the geometry of the robots will lead us to find a suitable expression which can be easily used for programming.

Figure 3.6: *Geometry of the third link in 3D.*

Figure 3.7: *Geometry of the third link in XZ-plane*

By looking to Figure 3.6 and Figure 3.7,  $L_{31}$  in xz-plane will be equal to:

$$L_{31xz} = \pm \sqrt{(L_{31})^2 - (Dby - Dpy)^2} \quad (3.16)$$

Then

$$\beta = \pm \arccos \frac{Dpx - q_3}{L_{31xz}} \quad (3.17)$$

And finally

$$\beta = \pm \arccos \frac{Dpx - q_3}{\sqrt{(L_{31})^2 - (Dby - Dpy)^2}} \quad (3.18)$$

It is noticed that  $\beta$  still dependent on  $q$ . This make the IK impossible to solve.  $\beta$  must be independent of  $q$ . A new concept for foundation of  $\beta$  which can be obtained from an auxiliary link  $L_{aux}$ . This auxiliary link is constructed from the triangular linkage formed between the platform and links of arm 3. The auxiliary link  $L_{aux}$  is the line starts from  $D_b$  and moves perpendicularly to the line connected between  $E_p$  and  $D_p$ .

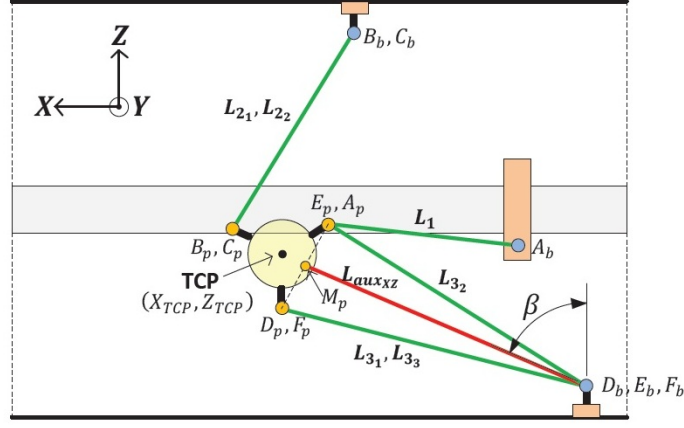

Figure 3.8: Explain of the auxiliary link in  $xz$ -plane  $L_{auxxz}$  [10]

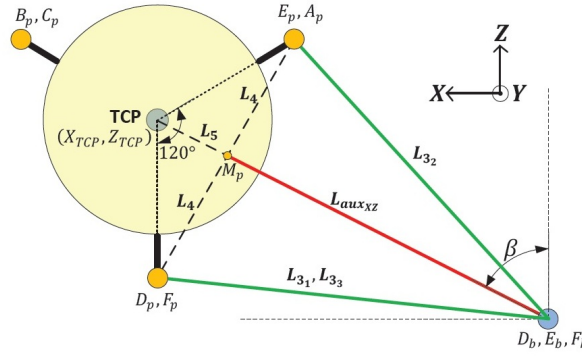

Figure 3.9: The auxiliary link in  $xz$ -plane  $L_{auxxz}$  includes needed parameters [10]

Figure 3.8 and 3.9 show the auxiliary link in  $xz$ -plane  $L_{auxxz}$   
By looking to figure 3.9:

$$\cos \beta = \frac{Z_{TCP} - Z_{Db}}{L_{auxxz} + L_5} \quad (3.19)$$

And

$$L_{aux} = \sqrt{(L_{31})^2 + (L_4)^2} \quad (3.20)$$

$L_4$  and  $L_5$  can be found by applying of the cosine theorem and fethaghors respectively which equal to:

$$L_4 = \frac{1}{2} \sqrt{(Z_{Dp})^2 + (Z_{Ep})^2 - 2Z_{Dp}Z_{Ep} \cos(120)} \quad (3.21)$$

$$L_5 = \sqrt{(Z_{Dp})^2 - (L_4)^2} \quad (3.22)$$

$$(3.23)$$

And from figure 3.10, it can be found that:

$$L_{auxxz} = \sqrt{(L_{aux})^2 - (Y_{TCP} - Y_{Db})^2} \quad (3.24)$$

Figure 3.10: *The auxiliary link in xz-plane  $L_{auxxz}$  [10]*

Applying of equation 3.20 leads to:

$$L_{auxxz} = \sqrt{(L_{31})^2 + (L_4)^2 - (Y_{TCP} - Y_{D_b})^2} \quad (3.25)$$

Finally  $\beta$  can found by:

$$\beta = \pm \arccos \frac{Z - Z_{D_b}}{L_{auxxz} + L_5} \quad (3.26)$$

Where all variables are known.

# Chapter 4

## Identification Method

Calibration:

Identification method is the main part of this project. A deep study has been done to choose a good method which can be suitable for calibration error. A MatLap program should be established to achieve this goal. Calibration error can be found depending on the links length  $L_1-L_6$  in the 5-DOF case and  $L_1 - L_3$  in the 3-DOF case. The link lengths are known. By using the laser tracker in experiments, the  $TCP$  position can be found. The link lengths also can be found analytically by IK. Comparing of the theoretical link lengths to the real link length will lead to find the lengths error. Before going to laboratory and experiments, it will not be difficult to find the  $TCP$  position.

In the beginning it can be established a program to return back the theoretical link lengths  $L_1 - L_3$  where  $X, Y, Z$  and  $C_1, C_2, C_3$  are the user inputs and the actuators position  $q_1, q_2, q_3$  have been found. The same program can be used when we use the laser tracker and experiments. After foundation of the error, a suitable method should be applied to achieve the calibration error. The IK for parallel robots leads to nonlinear equations. An optimization function such as FMINCON and LSQNONLIN is needed to achieve the calibration.

### 4.1 LSQNONLIN

LSQNONLIN is a good method to solve non-linear least squares problems. LSQNONLIN attempts to solve problems of the form:

$$X = \min \sum (FUN(X)^2) \quad (4.1)$$

where  $X$  and the values returned by  $FUN$  can be  $X$  vectors or matrices.

The IK function can be written in the form

$$[ Q_1 \quad Q_2 \quad Q_3 ] = IK(X, Y, Z, C_1 - C_3, L_1 - L_6) \quad (4.2)$$

It should be noticed that the optimization will be done during a path of the robots. The path means that the robot will be moved depending on selected of different points. This will be explained on Chapter 5. Let us choose a path beginning  $(X, Y, Z)$  and ending with  $(X^m, Y^m, Z^m)$  for  $(C_1 - C_3)$  to  $(C_1^m - C_3^m)$ . The IK for the path will be:

$$\begin{bmatrix} Q_1 & Q_2 & Q_3 \\ \vdots & \vdots & \vdots \\ Q_1^n & Q_2^n & Q_3^n \end{bmatrix} = IK \begin{bmatrix} X & Y & Z & C_1 - C_3 & L_1 - L_6 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ X^n & Y^n & Z^n & C_1^n - C_3^n & L_1 - L_6 \end{bmatrix} \quad (4.3)$$

The LSQNONLIN optimisation function will be in the form:

$$[L_1 - L_6] = \min_{L_1-L_6} \sum_{i=1}^3 (Q_i - Q_i^m) \quad (4.4)$$

The optimization will start with some lenk lengths. The square difference between the theoretical  $Q_i$  and the measured  $Q_i^m$  will be counted. Minimizing the error is the aim of the optimization. The link lengths will be the factor for referring to the error in the system.

LSQNONLIN implements two different algorithms: trust region reflective and Levenberg-Marquardt. Choose one via the option Algorithm: for instance, to choose Levenberg-Marquardt, set

$$OPTIONS = optimset('Algorithm','levenberg-marquardt') \quad (4.5)$$

and then pass OPTIONS to LSQNONLIN as it explains in [1].

$$X = LSQNONLIN(FUN, X_0, LB, UB, OPTIONS) \quad (4.6)$$

Equation 4.6 is the general form of LSQNONLIN in MatLab. The optimization starts at the matrix  $X_0$  and finds a minimum  $X$  to the sum of squares of the functions in  $FUN$ .  $FUN$  accepts input  $X$  and returns a vector (or matrix) of function values  $F$  evaluated at  $X$ . It should be noted that  $FUN$  should return  $FUN(X)$  and not the sum-of-squares  $\sum(FUN(X)^2)$ , where  $(FUN(X))$  is summed and squared implicitly in the algorithm.

The lower bounds  $LB$  and upper bounds  $UB$  define a set of lower and upper bounds on the design variables  $X$ , so that the solution is in the range  $LB \leq X \leq UB$ . The options  $OPTIONS$  minimizes with the default optimization parameters replaced by values in the structure  $OPTIONS$ , an argument created with the  $OPTIMSET$  function.

In our application, the results of LSQNONLIN are not acceptable. This is due to the LSQNONLIN find the first local minimum value of the function and return it as a minimum value. If  $LB$  and  $UB$  choosed to be so closed to the minimum value then the minimum value will be the same of the local minimum value and it will return a correct optimization value. In this case the result will not be enough for a good optimization. Increasing of the  $LB$  and  $UB$  will results many local minimum value and the optimization will return the first local minimum value.

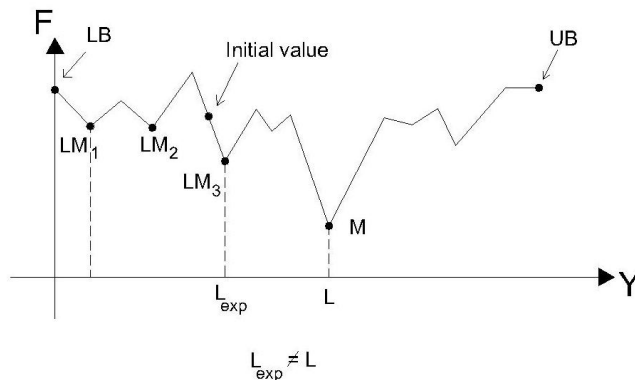

Figure 4.1: *Explaine of the principle work of LSQNONLIN - high range boundaries*

Changing of the OPTION parameter will help to gett a better optimization but not to solve the problem. For mor explain, let us see figure 4.1 and figure 4.2 which show the function by changing of  $Y$  while  $X$  is fixed. In figure 4.1 there is a high range between  $LB$  and  $UB$  which give a wrong optimization result. In figure 4.2 the  $LB$  and  $UB$  are too closed to the minimum value, This means that there is just one minimum value which will be the local and actually minimum value. At this case the result will be right.

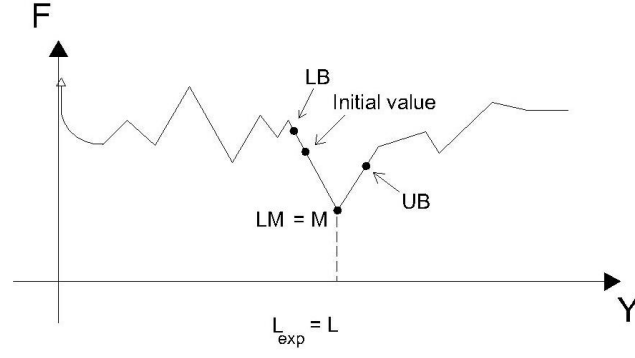

Figure 4.2: Explaine of the principle work of LSQNONLIN - closed boundaries

## 4.2 Complex Search Method

As it described before, the Gantary-Tau and other PKMs is difficult to calibrate the error manually. The Complex Search Algorithm are presented in this section. Reference [12] explained the Complex Search Method in an easy way and will be mainly used in this section.

### 4.2.1 Evolutionary Multi-Objective Optimisation

The method used in this thesis is based on evolutionary algorithm. Evolutionary algorithms are suitable for the Error Kinematic Modeling and Calibration because they deal simultaneously with a set of possible solutions that allow to find a set of candidates for the optimal result in a single run of the algorithm instead of having to perform a series of separate runs as it deals with the traditional mechanical programming method.

The complex search method is based on the evolutionary multi-objective optimisation concept. An example of multi-objective optimisation problem is given below:

$$\min [ f_1(par), \dots, f_k(par), f_{k+1}(par) ] \quad (4.7)$$

subject to

$$g_i(par) \leq 0 \quad (1 \leq i \leq r) \quad (4.8)$$

$$h_j(par) = 0 \quad (1 \leq j \leq s) \quad (4.9)$$

$$par^L \leq par_p \leq par^U \quad (1 \leq N_{params} \leq N_{pop}) \quad (4.10)$$

Where  $k$  is the number of objective functions  $f_k(par)$ ,  $par$  is a vector of  $N_{params}$  optimisation parameters (solutions),  $g_i(par)$  and  $h_j(par)$  are each of the  $r$  inequality and  $s$  equality problem constraints,  $par^L$  and  $par^U$  are lower and upper limits of the optimisation parameters. The constraints are considered as a new objective constraints handling function  $f_{k+1}(par)$ .

In multi-objective optimisation, objectives are not comparable with respect to their magnitude and value and may conflict, where some objectives can not be increased without a decreasing of others. The result of a multi-objective optimisation is a set of trade-off solutions which are considered to be suitable for all objectives. Due to the impossibility of achieving optimal values of all objectives simultaneously, multiple criteria decision making always involves a choice problem, for example the weight functions are used to define a level of importance of the objectives. The final solution represents a compromise between the different objectives and depends on the preferences of the decision maker.[12].

### 4.2.2 Concept and Stages

In this section, the concept of work of the Complex Search Method will be explained step by step. MatLap files for Complex Method and Fitness Function will be included in the appendix. These files show an

explain for the mechanism of work of each step.

The Complex Search Method consists of several stages:

- Generate the the initial population  $N_{pop}$  from the number of the optimisation parameters  $N_{params}$ . The population  $N_{pop}$  is equal to  $2^{N_{params}} + 1$ .
- Found of root mean squared error. Then minimize the error by maximizing the function.
- Choose the boundaries upper and lower limits  $par^U$  and  $par^L$  and the number of times to evaluate the maximization of the error  $gen_{max}$ .
- Evaluate the objectives. The worst and the best results of the error are identified as  $x_{worst}$  and  $x_{best}$  respectively in each iteration.
- Calculate the centroid of the remaining error  $x_{centroid}$  in each iteration.
- Mirror worst result of error  $x_{worst}$  through the centroid  $x_{centroid}$ .
- The new mirror result  $x_{new}$  will be checked to be not out of boundaries. Apply the maximization function and check the new mirror result. If it still worst, move it toward the best result by reset number of iterations  $k_r$  and increment it.
- Increment the generation  $gen$  and repeat the previos steps.
- Let the complex function initialize the maximization function and the population randomly.

Figure 4.3: *Mirror of the worst result through the centroid.*[12]

To explain the implementation concept of the complex search method, consider Figure 4.3 where  $y_c$  is the centroid,  $y_j$  is the worst result,  $y_{j(new)}$  is the mirror of the worst result, and  $n$  is the number of the results  $y$ . As it explained on the stages above, the centroid  $y_c$  will calculated and it is defined to:

$$y_c = \frac{\sum_{i \neq j}^n y_i}{n - 1} \quad (4.11)$$

When the worst result  $y_j$  found, it will be mirrored through the centroid  $y_c$ . The new mirrored result  $y_{j(new)}$  is equal to:

$$y_{j(new)} = 1.3 * (y_c - y_j) + y_c \quad (4.12)$$

The new mirrored result  $y_{j(new)}$  will move toward the current best result more or less strongly depending on following definitions:

$$y_{j(new)} = 0.5 * (y_j + \epsilon * y_c + (1 - \epsilon) * y_k) \quad (4.13)$$

$$(4.14)$$

$$\epsilon = \frac{n_0 \frac{n_0 + n_r \epsilon p - 1}{n_0}}{n_0 + n_r \epsilon p - 1} \quad (4.15)$$

Where the  $y_k$  is the best result,  $n_0$  is a tuning parameter which is normally equal to 4 to 5,  $n_{rep}$  is the number of iterations. In the complex search algorithm the parameters  $n_0$  and  $n_{rep}$  are used to switch between the worst and the best results. Figure 4.4 shows the algorithm of the complex method.

## Chapter 5

# Cartesian Paths for Identification

The TCP of the Gantry-Tau will be moved from place to another depending on the new user input cartesian point. A set of points is called the path which will control the movement of TCP from point to point by entering different a amount of points between them. The path should be optimised depending on the user requirement. There is many requirements for creating a sufficient path. It should be considered the work area of the Gantry-Tau. In Chapter 3, 8 possible solution for each point has been explained. The optimal path should keep the actuators in the same side-hand solution. This will make the motion of TCP during the path smooth and will avoid the rigidity when an actuator has to move long way to oblige the arm changing direction between right-hand solution to the left-hand solution or the converse. This unrequired disturb can happen when the TCP want to reach a critical points. A critical points are those points that the Gantry-Tau can reach them with less than 8 possible solution. Some of them can be just one solution to reach them. It means that, if it is obligatory for the designer to reach those points, he should take in account to choose the right solution for the beginning point. The optimisation will make it easy enough to avoid rigidity and will make it easy to choose the shape of movement between sending and reaching points.

### 5.1 Straight Line

A MatLab program has been established to create a straight line efficient path. The program chooses a set of points with equal distances between a point and the next one. Applying the Inverse Kinematic Model will calculate the position of each base actuator. It will also check for the right-hand and left-hand solution for each arm. If there is a change on the direction, the point will be avoided.

The straight line path *op.tracker* is presented by TCP *XYZ* coordinates, actuator positions are presented by matrix *op.enc*, and the configurations given by matrix *op.config* as shown below:

$$op.tracker = \begin{bmatrix} X & Y & Z \\ 2.1000 & 0 & 1.4500 \\ 1.9600 & 0.0600 & 1.3850 \\ 1.8200 & 0.1200 & 1.3200 \\ 1.6800 & 0.1800 & 1.2550 \\ 1.5400 & 0.2400 & 1.1900 \\ 1.4000 & 0.3000 & 1.1250 \\ 1.2600 & 0.3600 & 1.0600 \\ 1.1200 & 0.4200 & 0.9950 \end{bmatrix} \quad (5.1)$$

$$op.enc = \begin{bmatrix} Q_1 & Q_2 & Q_3 \\ 1.2316 & 1.2611 & 1.5972 \\ 1.0388 & 1.1325 & 1.2883 \\ 1.0231 & 0.9338 & 1.2141 \\ 0.7710 & 0.8978 & 0.8240 \\ 0.2959 & 0.6004 & 0.7293 \\ 0.4357 & 0.2118 & 0.8090 \\ 0.3537 & 0.6327 & 0.2256 \\ 0.0305 & 0.0271 & 0.3545 \end{bmatrix} \quad (5.2)$$

$$op.config = \begin{bmatrix} C_1 & C_2 & C_3 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix} \quad (5.3)$$

## 5.2 Circle

By the same way used to find the straight line path on 5.1, A MatLab program has been established to create a circle line efficient path. This path created to move on  $XZ - plane$ ,  $Y$  is kept equal to zero. The radius of the circle choosed to be 0.5 m.

The circle path given from the result of the program are:

$$op.tracker = \begin{bmatrix} X & Y & Z \\ 0.7 & 0 & 0.8 \\ 1.2 & 0 & 1.3 \\ 1.7 & 0 & 0.8 \\ 1.2 & 0 & 0.3 \end{bmatrix} \quad (5.4)$$

$$op.config = \begin{bmatrix} C_1 & C_2 & C_3 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix} \quad (5.5)$$

# Chapter 6

## Simulations and Results

In this chapter the simulation and the result of the error calibration of the Gantry-Tau PKM will be inserted. As it explained on the previous chapters, the 3-DOF inverse kinematic model has been established. The error will be equaled to the root of squared mean of the difference between the original link length and the calculated from the laser tracker collected data. The error model will be in this form:

$$E = \sqrt{\left(\frac{Q - \hat{Q}}{2}\right)^2} \quad (6.1)$$

Where  $E$  is the error,  $Q$  is the 3-DOF inverse kinematic model using the original link lengths, and  $\hat{Q}$  is the 3-DOF inverse kinematic model using the original calculated link lengths from the tracker.

The error model function  $EMF$  will minimize the error by maximizing the error  $E$ .

$$EMF = \sum_1^n E \quad (6.2)$$

Where  $n$  is the number of the points in the generation path which applied.

This error model function will be used by the complex search algorithms and return the results.

The number of error parameters  $N_{params}$  is equal to 3. These error parameters are  $L1$ ,  $L2_1$ , and  $L3_1$ . The number of population  $N_{pop}$  is defined as:

$$N_{pop} = 2^{N_{params}} + 1 \quad (6.3)$$

$$N_{pop} = 9 \quad (6.4)$$

Table 6.1: Simulation Results for straight line path by changing number of generation.

Total time (sec)	1.4677	13.9037	70.0079

The generated straight line path which has been discussed in 5.1 has been used to calibrate the error. By changing the boundaries and the generation times, the complex still show a good results. Table 6.1 shows that the complex search method can minimize the error to zero by changing the number of generation.

The second column in Table 6.1 shows that the number of generation is not enough to minimize the error to zero and get the same original link lengths, while increasing the number of generation make the result better.

Table 6.2 shows that the complex search method can minimize the error to zero by applying different boundary limits. A high range limits have been applied where all gives a good results and minimize the result to zero.

## Chapter 7

# Conclusions and Suggested Further Work

### 7.1 Conclusions

The goal of this thesis was to apply a suitable technique for calibration error. This goal requires initially to model the kinematic errors of the Gantry-Tau PKM. The Gantry-Tau PKM consist of 6 links with 5-DOF. From the early stages of the project, it became clear that building a full kinematic model in both Forward and Inverse Kinematics with all error parameters is taken much time. Because of that, The Gantry-Tau considered to be 3-DOF and contains 3 arms. A 3-DOF inverse kinematic model have been established and the project became focussed on the Calibration error of three parameters. These 3 parameters chosen to be the error on the 3 arms. Chosen of an efficient optimisation method was of importance.

LSQNONLIN gave unacceptable results and worked just for a very closed boundaries. The optimisation should be worked in a high range between the upper and lower limits and the method algorithm must be able to minimize the error in this high range.

The Complex Search Method was an efficient method. It has been applied for one point and gave a positive results. Then, cartesian paths are established using the inverse kinematic model. These paths were not highly accurate optimisation paths, but the complex method applied on these paths. Due to external constraints, there was no opportunity to collect experimental data. Experimentation would strengthen the merits of the project, but there is not enough time for generation of a highly accurate path and experimentation. Simulation by MatLab program was used instead of experiments. The results that have been achieved are highly relevant and enable the advancement of further works in the area of calibration error of Gantry-Tau PKM.

This thesis has been subjected to the complex search method to effectively calibrate the Gantry-Tau error, but the clearest conclusion to be found from this project is that there is an abundance of work to be done in order to achieve high strongly error calibration of the Gantry-Tau PKM. The Complex Search Method is an efficient optimisation method which can apply perfectly on the calibration error of the PKM. 3-DOF Inverse Kinematic model is a consideration to make the work easy. The concentration were on the optimisation and identification method. Since the complex search method works well on the 3-DOF, it will be easy to apply for advanced 5-DOF inverse kinematic model with more error parameters.

An advanced modelling with a higher number of error parameters can be established. These error parameters can be joint errors, platform errors and potentially opening arm lengths error parameters to form a full Kinematic Error Model for the Gantry-Tau. In the same time, collected data from experimental and laser tracker can be used instead of simulation. These two points can make the results strongly acceptable and more effective.

## 7.2 Suggested Further Work

In this section, it will be mentioned some points that can be suggested for those who are interested to work on the calibration error for Gantry-Tau.

- This thesis and the Matlab programming codes have been built in an easy way to replace the simulation with the experiment results. The experiments is suggested to be done.
- Optimisation of an effective path is an important part to get the experiments work correctly. Choose an optimisation technique is suggested for different paths.
- Gantry-Tau calibration error can be extended and applies to a high number of error parameters when the Gantry-Tau considered to be 5-DOF. Using of complex method technique for PKM kinematic error model calibration in PKM is suggested.
- Using of LSGNONLIN technique for calibration error is not an impossible idea. Changing of the options for this algorithm will not be enough to make it work correctly in PKM applications. The searcher should add some codes to this algorithm. These codes make the algorithm read the real minimum values and not the local minimum value. The Upper and Lower limits (boundaries) must not be closed to each other.

 LSQNONLIN Function

Into lsqnonlin we will send measured X,Y,Z positions from laser tracker  
 and measured motor values q1,q2,q3  
 The optimisation should return L1-L6

X0 = [1.4];    Initial link lengths  
 LB=[1];    Lower limit  
 UB=[2];    Upper link length limit  
 OPTIONS=optimset('Display','on','TolFun',1e-100,'TolX',1e-100,'MaxFunEvals',1000);

P.X=X;    TCP Measurements from laser tracker  
 P.Y=Y;  
 P.Z=Z;  
 P.Q=Q;    We are pretending this is a measurement of motor positions  
 P.S=S;  
 P.C=[C1 C2 C3];

$L_{opt} = \text{LSQNONLIN}(@L \text{ myfun}(L,P), X0, LB, UB, OPTIONS)$

.....  
 .....  
 Myfun Function

```
function F = myfun(L,P)
P.S.L1 = L(1);
P.S.L2_1 = L(2);
P.S.L2_2 = L(2);
P.S.L3_1 = L(1);
P.S.L3_2 = L(1);
P.S.L3_3 = L(1);
```

The Q below is estimated from measured TCP position  
 $Q = \text{invkin}(P.S, P.X, P.Y, P.Z, P.C(1), P.C(2), P.C(3))$

```
F(1)=P.Q(1)-Q(1);
F(2)=P.Q(2)-Q(2);
F(3)=P.Q(3)-Q(3);
```

Optimisation function: difference between measured P.Q and estimated Q

```

from P,X,Y,Z
F(1) = 1e1*(P.Q(1)-Q(1));
F(2) = 1e1*(P.Q(2)-Q(2));
F(3) = 1e1*(P.Q(3)-Q(3));
